Abstract

We show that the lowest-order QCD calculation in a simple model of elastic vector-meson production does reproduce correctly the ratios of cross sections for ρ , ϕ and J/ψ (measured by H1¹⁾ and ZEUS²⁾), both in photoproduction and in high- Q^2 quasi-elastic scattering. The mass and Q^2 dependence of the cross sections is reproduced as well. We also examine the lower-energy data, and see that the energy dependence of the cross section does not depend on Q^2 , and that a comparison with ρ and ϕ data from NMC³⁾ suggests a soft pomeron intercept.

We⁴⁾ attempt to model Elastic Vector-meson production in the HERA kinematical range, i.e high energy and low t . Several models⁴⁻⁶⁾ have been proposed to describe this process. But so far, there has not been a model applied to the full range of masses and Q^2 . This is the object of our model⁴⁾.

The process that we study is the elastic interaction between a (virtual) photon and a proton: $\gamma^*p \rightarrow Vp$. V is the vector meson of mass M_V and can be a ρ , ϕ or J/ψ . The differential cross section of this process is given by: $d\sigma_{\gamma p}/dt = |A|^2/(16\pi w^4)$, where $w^2 = (P+q)^2$ is the centre of mass energy in the γ^*p system.

Our model for exclusive vector-meson production includes three simple sub-models: we use a non relativistic model for the vector meson, where the quark and the anti-quark share the V -momentum equally and have the same mass equal to $\frac{M_V}{2}$, the colour-singlet exchange is modeled à la Low-Nussinov (two perturbative gluon exchange), and we shall only consider the constituent quarks of the proton. This leads us to two form factors for the proton which enable us to cancel the infrared singularity that would result from the pole in the gluon propagator. In the following we call $\hat{w}^2 \equiv (p+q)^2$, where p is the parton four-momentum. Moreover, we work in a Lorentz frame such that parton masses can be neglected. The key point in the calculations is to get the leading term in the high-energy

Figure 1: The two diagrams accounting for the transition $\gamma^* \rightarrow V$. The dashed line represents the cut which puts the intermediate state on-shell.

limit correctly, i.e. $\hat{w}^2 \gg m_V^2, Q^2$ (where $Q^2 = -q^2$ is the off-shellness of the photon).

In principle, 72 diagrams contribute to the amplitude. However, with the use of those simplest sub-models and in the high-energy limit, the calculation of each part of the amplitude can be greatly simplified and we end up only with two diagrams shown in Fig.1. It will come out that the imaginary part of the amplitude is proportional to $\hat{w}^2$. Crossing symmetry and analyticity then imply that the amplitude is purely imaginary, up to terms of order $1/\hat{w}^2$, because the exchange is $C = +1$. In order to calculate this imaginary part of the amplitude, we use Cutkovsky's rules, putting intermediate quarks on-shell and replacing their propagator by a delta function.

Now taking everything into account, we obtain the following expressions for the amplitude, for the various possible helicities:

$$\begin{aligned} \mathcal{A}(T \rightarrow T) &\propto i\hat{w}^2 R \alpha_S^2 \\ &\times \int \frac{d^2k}{k^2(k-\Delta)^2} \frac{[\mathcal{E}_1(t) - \mathcal{E}_2(k, k-\Delta)] [k \cdot (k-\Delta)]}{(t - m_V^2 - Q^2 + 4 k \cdot (k-\Delta)) (m_V^2 + Q^2 - t)} \end{aligned} \quad (1)$$

$$\mathcal{A}(L \rightarrow L) = \frac{\sqrt{Q^2}}{m_V} \times \mathcal{A}(T \rightarrow T) \quad (2)$$

The first T (L) refers to the polarisation of the photon and the second to that of the meson. As previously advertised, this answer is proportional to $\hat{w}^2$, and is thus purely imaginary. One also finds that the longitudinal amplitude is proportional to Q times the transverse amplitude and that the helicity violating amplitudes $\mathcal{A}(L \rightarrow T)$, $\mathcal{A}(T \rightarrow L)$ are nonleading in energy, i.e. down by $1/\hat{w}^2$.

The resulting differential cross section is given by:

$$\frac{d\sigma}{dt} = \frac{d\sigma_T}{dt} + \varepsilon \frac{d\sigma_L}{dt} = \frac{R}{16\pi\hat{w}^2} [|\mathcal{A}(T \rightarrow T)|^2 + \varepsilon |\mathcal{A}(L \rightarrow L)|^2] \quad (3)$$

with ε the polarisation of the photon beam: $\varepsilon \approx 1$ at HERA and $\varepsilon \approx 0.75$ at NMC. Clearly this model cannot say anything about the energy dependence of the cross section. We shall assume that it comes in as a factor, R (Regge factor), and check whether the latter is mass- or Q^2 -dependent.

Figure 2: (a) Cross sections as functions of Q^2 , compared with data from H1 ¹⁾ and ZEUS ²⁾ at $\langle w \rangle \approx 100$ GeV; (b) Cross sections compared to lower-energy EMC and NMC data ³⁾, at $\langle w^2 \rangle \approx 200$ GeV².

We first give the results that we obtain for the various cross sections measured by ZEUS and H1. In Fig. 2 we show the dependence on Q^2 and m_V of the integrated elastic cross section $\sigma(Q^2)$. We see that a common (Regge) factor is consistent with the data taken at HERA, as shown in Fig. 2(a). We insist on the fact that this factor is independent both of Q^2 and of m_V , as one would expect within Regge theory. Although we see no reason why our model should work in photoproduction, it turns out that our curves do go through the photoproduction points. The result of a fit $\sigma \propto (Q^2)^{-n}$ at large Q^2 , gives $n_{\rho, \phi} = 2.5$ and $n_{J/\psi} = 1.5$ which is in good agreement with experiments.

In the ratio of cross sections, some of the systematic uncertainties cancel, and the reproduction of that ratio is a more stringent test of our model, especially as the normalisation then drops out of our prediction. We show in Fig. 3(a) the result of such a comparison. Again, we see that our model fares well, even in photoproduction.

Other results are for the differential cross section. To illustrate the effect of the curvature, we compare in Fig. 3(b) our results with the data for ρ photoproduction in H1. We see that, here again, our curve reproduces the data fairly well, and indicates that $d\sigma/dt$ is *not* an exponential.

Finally, we can now examine the w^2 -dependence of the cross sections, and compare with NMC and EMC data. We have seen that at HERA, the Regge factor does not depend either on the meson mass or on Q^2 . We adopted the same philosophy when fitting to lower-energy cross sections from EMC and NMC³⁾, and we observed that ρ data point to a soft pomeron intercept. There may be a

Figure 3: (a) Ratio of cross sections as functions of Q^2 at $\langle w \rangle \approx 100$ GeV, compared with data from H1¹⁾ and Zeus²⁾; (b) Photoproduction differential cross section $d\sigma/dt$, compared with H1 data¹⁾.

problem with the smallness of the ϕ cross section at NMC which implies a larger intercept. We do not believe that much can be concluded from the J/ψ data, which seem to have an inelastic background. We show in Fig. 2(b) the curves which correspond to an intercept of 1.16. We see that the fit is reasonable for the ρ and the ϕ . We can see that there is no sign in either ρ or ϕ data of a Q^2 dependence of the intercept.

To sum up, both the m_V and the Q^2 -dependence of the cross sections, as well as the t -dependence can be understood in a simple QCD model. The HERA data indicate that the Regge factor does not depend either on Q^2 or m_V . The comparison with NMC ρ data points to a soft pomeron intercept. The only problem we have is the prediction of the ratio σ_L/σ_T , which may be resolved by the introduction of Fermi momentum.
